## PREFACE

This technical report is a reproduction of a thesis submitted in partial fulfillment of the requirements for the degree of Master of Science in Engineering in the Department of Geodesy and Geomatics Engineering, May 1995. The research was supervised by Dr. Adam Chrzanowski, and funding was provided partially by the Natural Sciences and Engineering Research Council of Canada, Maraven S.A. of Venezuela, and the University of New Brunswick.

As with any copyrighted material, permission to reprint or quote extensively from this report must be received from the author. The citation to this work should appear as follows:

#### Abstract

The Costa Bolivar Oil Fields, located along the east coast of Lake Maracaibo, contain some of the richest oil deposits in South America. Exploitation of these reserves, located some 300 m to 1000 m below the lake surface, has led to some considerable subsidence along the east coast shore. The accumulated subsidence since 1932 has resulted in the land mass being some 4 m below the lake surface. Consequently, a 46 km dyke was constructed and maintained to protect the low lying inhabited area and production utilities.

Up until 1986, monitoring of the dyke and surrounding area utilised conventional geodetic measurements. At this time, UNB proposed that the Global Positioning System (GPS) could provide some significant savings by replacing some of the lengthy and costly levelling surveys. Since 1987 both GPS and geodetic levelling data have been collected periodically to assess the performance of the GPS in this project. Prior to 1993, problems with the GPS data and its processing have limited the analysis. An incomplete satellite constellation, noisy single frequency data, and systematic biases in both the data and the processing software, have all contributed to a problematic study.

This thesis has evaluated the GPS data to date and assessed its usefulness for subsidence studies in this area. It has revealed that the present methodology employed has produced very promising results in the last two years, but some additional strategies are still required to gain full confidence in the GPS results.

## Acknowledgements

I wish to express my sincere appreciation to all those who have aided in carrying out this research. First and foremost to my supervisor, Professor Adam Chrzanowski, whose knowledge, guidance and understanding was unremitting, and greatly appreciated. Professor Alfred Kleusberg, for his support in the early days and his guidance in the field of the GPS. Julio Leal, Juan Murria, Miguel Pedroza and all the personnel at Maraven S.A., who made my trip to Venezuela possible, and a very valuable experience. Jacek Grodecki, Atilla Komjathy and Mark Caissy for their advice in the areas of deformation studies, GPS and MINQE, respectively. And finally, to all the fellow graduate students and staff who provide the atmosphere and spirit within which to work.

Funding was provided in part by the University of New Brunswick and the Natural Sciences and Engineering Research Council (NSERC) in Canada, and Maraven S.A. in Venezuela.

This thesis is dedicated to my family in England; Will, Janet, Dominic and Katrina Walford.

## Chapter 1

## Introduction

### 1.1 Lago De Maracaibo

The Costa Bolivar Oil Fields extend some 120km along the east coast of Lake Maracaibo, spanning the areas of Cabimas, Tia Juana, Lagunillas, Bachaquero and Mene Grande (figure 1.1). The topography in this region is characterised by marshy lowland flats extending some hundreds of kilometres, which are, on average, only a few metres above the lake surface level.

Long term oil exploitation, dating back to 1914, has resulted in extensive ground subsidence, reaching 5 m in places. Present rates of vertical movement have been up to $20 \mathrm{~cm} /$ year. Consequently, a portion of the subsidence zone now lies 4 m below the lake surface. A 46 km protective dyke was constructed and maintained to protect the low lying inhabited area and production facilities. Ground subsidence has also increased the amount of water in the lowland marshes, thus an irrigation system was implemented to pump the water back into the lake [Murria, 1988].

## Costa Bolivar Oil Fields

Figure 1.1. Relative location of the Costa Bolivar Oil Fields [after Puig, 1984].

### 1.2 Monitoring Scheme

In 1929, when the first signs of deformation were noticed, a monitoring scheme was established, which up until 1987, has predominantly utilised precise geodetic levelling. The need for a monitoring scheme is three fold.

- To update the irrigation system, which consists of a number of downhill channels, ferrying the water to the pumping stations along the dyke. The location and grade of the channels is dictated by the subsidence.
- To monitor and upgrade the height of the dyke.
- To study the effects of the oil extraction and correlate the subsidence with the volume of extracted oil.

A main levelling network of some 1436 benchmarks covers the area between Tia Juana and Bachaquero (figure 1.2). It consists of three primary lines of first order class two (U.S. specifications) covering 618.9 km , intertwined with 553.7 km of second order class two densification lines. Two additional sub-networks are located in Cabimas and Mene Grande creating 188 stations, and a further 160.1 km and 67.3 km of first and second order lines, respectively. Full re-observation of the levelling network is carried out on a biannual basis. In the present day this method has become costly and lengthy. A complete overview of the levelling network and surveys, up to 1988, can be found in Leal [1989].

To date, precise geodetic levelling has provided consistently good results, achieving an accuracy of $20-30 \mathrm{~mm}$ (@95\% confidence) for the subsidence determination [Leal, 1989].

Figure 1.2. Main Levelling network [after Leal, 1989], showing accumulated subsidence since 1929.

The expanding size of the exploitation area has led to a very large network covering some $1300 \mathrm{~km}^{2}$, encompassing 1624 benchmarks. The re-survey of this network takes six levelling crews approximately two months to complete.

In 1984, Maraven S.A., one of the state owned oil companies working in the area, and responsible for the monitoring of ground subsidence and stability of the dyke, undertook the task of maximising productivity and cutting back costs. In 1986, the Department of Surveying Engineering at the University of New Brunswick (UNB) proposed that the Global Positioning System (GPS), if accurate enough, could provide considerable savings in both time and manpower, over the conventional levelling surveys, in the ground subsidence studies.

It was proposed in 1986, [Chrzanowski et al, 1989] that the use of the GPS could:

- Replace the long lines of first order levelling, connecting the subsidence area to the three datum benchmarks, established in a presumably stable area (figure 1.2).
- Provide a frame work of points to be densified with the second order levelling, thus disbanding the first order levelling surveys, and providing savings up to $30 \%$ [Leal, 1989].
- Provide additional information on the horizontal movements.

In 1987, two test surveys were performed using single frequency GPS, in the Tia Juana/Lagunillas area, covering one third of the primary levelling network. The analysis of
the GPS survey revealed that the accuracy attained in Venezuela was considerably lower than a similar style survey conducted in Canada. The less precise results were attributed to the hot and humid climate experienced in Venezuela, which increased the tropospheric effects. Despite the results being slightly worse than desired, a full implementation of the GPS in the subsidence area was introduced in April 1988, for further more detailed analysis. Yearly GPS campaigns after this date created expansions to the network, which by 1994, involved 26 stations, spanning the five main oil fields, from Cabimas down to Mene Grande (figure 1.3). A more detailed description of the GPS network is given in chapter two.

### 1.3 Studies To Date

The application of the GPS in this area has been studied recently by the following people and organisations.

Chrzanowski et al [1989] published results of the 1987 test surveys and of the first full GPS campaign of 1988, deriving mathematical models for the combination of GPS and levelling in ground subsidence studies.

Leal [1989] studied the integration of Levelling and GPS data for subsidence monitoring. He concluded at the time, that some inconsistencies between the two methods existed, possibly a systematic effect, that would be better estimated under a future stronger GPS system.

Pedroza [1989] examined the effects of the troposphere and satellite geometry in the GPS applied to ground subsidence in the Lake Maracaibo area. He concluded that at the time, the tropospheric effect was significant on low elevation satellites, and different geometry of satellites also significantly affected the baseline results. Local atmospheric measurements found no evidence of local variations.

Chen and Chrzanowski [1990] studied the integration of the GPS and levelling in ground subsidence studies, developing mathematical algorithms for the estimation of the GPS systematic biases and observation weights. Using the subsidence data up until 1988, they successfully filtered out the GPS biases and derived estimates for the GPS heights, for moderate to hot and humid climates.

Usher Canada Ltd. and Coler and Colantonio Inc. [1990] assisted UNB and Maraven S.A. with the two GPS campaigns of 1988 and 1990, respectively, but had trouble finding meaningful results, concluding that the 1988 data was of poor quality. The use of single frequency receivers, a lack of baseline redundancy and a minimal number of satellites in each campaign, dictated the low accuracy of the results

Chrzanowski et al [1991] studied the results from the 1990 and 1991 data sets, and found significant rotations between the two campaigns, about all three axes through the fixed point. The largest was a 1 " rotation about an east/west axis. They concluded that
unmodelled ionospheric refraction and the systematic effects of the troposphere, as well as biases in the fixed co-ordinates had most likely contributed to the rotation.

Westrop [1991] investigated the 1990 and 1991 campaigns using more sophisticated GPS software (UNB's DIPOP) and modelling techniques to evaluate the various errors and systematic effects, causing such noisy data. She concluded that most of the noise was caused by the troposphere. Different tropospheric models were implemented in the processing, but none could reduce the noisiness of the data. Systematic errors in the GPS were also detected, causing rotations between surveys. Their source however, was unidentified.

Chrzanowski and Chen [1992] published a paper on the systematic errors of GPS baselines and their effect on ground subsidence studies. They used the 1990 and 1991 data sets as a case study, to model the biases, and develop a strategy for minimising the effects in deformation studies, concluding that the fiducial point approach should be utilised ideally.

The author has been involved in the reprocessing and evaluation of the five most recent GPS campaigns, since July 1992, hoping that the study would reveal in more detail some of the sources causing such noisy data and some of the systematic effects in the GPS results, particularly from the more recent campaigns of 1992 to 1994. These campaigns performed by Maraven S.A. were observed with dual frequency receivers, and utilised all the experience gained in the previous years.

Figure 1.3. Costa Bolivar GPS network.

### 1.4 Thesis Objective

The objective of this author's research was to study some of the GPS campaigns to date, namely the latter surveys of 1990 to 1994. More emphasis has been placed on the years 1992 to 1994, where the author had much more involvement in the data processing stage. Previous studies of the 1990 and 1991 data have shown certain systematic biases to exist [Chrzanowski et al, 1991; Chrzanowski and Chen, 1992]. This report examines whether these biases still exist, under a more fully implemented satellite constellation, and searches for the cause of such effects. Are they due to the GPS errors, propagation effects or software processors? Finally, an assessment of the results and accuracy achievable in this equatorial region, with the present network and observing/processing strategies currently being used, has been made. Recommendations on future campaigns are presented.

As mentioned in section 1.2, precise levelling has provided subsidence results with an accuracy of $20-30 \mathrm{~mm}$ (@95\%), or $15-20 \mathrm{~mm}$ (@95\%) for the absolute heights of each campaign. Thus the approximate accuracy for one campaign is $7-10 \mathrm{~mm}$ (@68\%).

It is expected, that if the GPS can give an absolute station error ellipse of $\leq 15 \mathrm{~mm}$ (@68\%) for a single campaign, then its use in establishing a framenet for the levelling surveys could be justified [Leal, 1989].

### 1.5 Author's Contribution

Leading on from the previous studies, the author has carried out the following:

- Analysed the data for systematic effects, specifically the ionospheric delay and multipath.
- Analysed the baseline results of the three most recent campaigns, and assessed the baseline errors using the MINQE technique.
- Investigated the effects of using two different commercial style GPS processors, and various different solution types, both single and dual frequency, finding systematic biases and differences to still exist in all the solution types.
- Analysed the GPS results from 1990 to 1994 for subsidence, after removing some of the above biases, achieving consistent results in the horizontal component, regardless of the processing strategy, and promising results for the vertical component, from the last two campaigns.
- Derived an update for the overall optimum accuracy achievable with the present scenario.

### 1.6 Thesis Outline

This thesis is purely concerned with the application of the GPS in the Lago de Maracaibo area. Although the campaigns from 1990 to 1994 will be used in the analysis of subsidence, only the data from years 1992 to 1994 will undergo scrutiny. A discussion of the GPS data to date is given in chapter two.

Many problems were encountered with the GPS data and results, in most of the campaigns. Some of these problems can be attributed to the systematic biases and errors in the GPS data. Chapter three gives some background into this area.

All the campaigns 1990 to 1994 were observed using Trimble ST or SST receivers. However, data processing was carried using two different software processors; Trimble's Trimvec Plus and Ashtech's Geodetic Post Processing Software, using a variety of processing solution types. These are discussed in chapter four.

An assessment of the satellite data quality of four campaigns was made using the program Quality Check available from UNAVCO [UNAVCO, 1993]. The results of the analysis are presented briefly in chapter five.

The results of the processing in which the author was involved are presented and discussed in chapter six. The campaigns of 1992 to 1994 are shown, as well as the test baseline results for 1992. The results for the prior campaigns are documented, but not discussed in detail. A comparison of the final adjusted co-ordinates between campaigns produced some interesting biases, especially between different solution types. These systematic biases are discussed. It is common knowledge that the results from commercial GPS processors often contain highly over optimistic standard errors for the baseline components. The results of an investigation into an alternative weighting scheme, using Minimum Norm Quadratic Estimation (MINQE), is also presented.

Analysis of the displacements is carried out for the campaigns 1990 to 1994, and the results are presented in chapter seven. Subsidence displacements were broken down into their respective horizontal and vertical components, and examined after the removal of systematic biases.

Finally, conclusions and recommendations are drawn on the last five campaigns of GPS data, and presented in the last chapter.

## Chapter 2

GPS Surveys to Date

### 2.1 GPS Campaigns

Since its proposal in 1986, GPS data has been collected on and off for eight years, culminating in a network of 26 stations covering an area of $2100 \mathrm{~km}^{2}$, encompassing the five main oil reserves from Cabimas to Mene Grande (figure 1.3).

The first so called test surveys were carried in the Tia Juana area, by UNB and Maraven, S.A., in April and October of 1987. Simultaneous precise levelling was carried out for a comparison. Optimistic results were obtained under a limited constellation, during short windows with relatively poor receivers by today's standards. Considering that all the problems would be ironed out in the future campaigns, 1988 saw the go ahead of a much fuller network to replace parts of the primary levelling network. This was considered the first of the yearly campaigns to be undertaken using the GPS. All data was collected using Wild-Magnavox WM101 single frequency receivers, with the help of Usher Canada Ltd, who also did the processing using the PoPS 2.01 software [Frei et al, 1986]. Overall, the above problems during both of the test surveys reduced the observation's significance.

The second survey contained very noisy data, giving ambiguity fixing problems. Ionospheric disturbance was considered the most likely cause.

Leal [1989] concluded that the expected accuracy in the height component was 29 mm (@68\%) for a single campaign with the GPS, which is considerably worse than the desired $10-15 \mathrm{~mm}$ (cf. section 1.4).

The next campaign was in 1990, to coincide with the bi-annual levelling data, and was conducted using more sophisticated Trimble 4000ST and Trimble 4000SL receivers, again single frequency. This campaign was expanded to 20 stations covering much of the oil exploitation area. Observation periods were for two hours on average, and conducted at various times in the day.

The campaign of 1991 was broken down into three periods, the first in February, then March and finally August. The first two periods covered most of the 1990 GPS network, but with a very small amount of redundancy. During August newly upgraded dual frequency receivers, Trimble Geodetic Surveyor II 4000SST were employed, but only sixteen baselines (out of 60 ) were re-observed. This last section has not been dealt with in this report. The first two periods were combined together, into one epoch adjustment. The campaigns of 1990 and 1991 were conducted and processed with the help of Coler and Colantonio Inc. [1991]. They reported that although observation procedures and the constellation had improved in 1991, the "data had been tough to work with", and eight
baselines had to be re-observed. The report quoted possible causes to be: "varying atmospheric conditions (effecting the tropospheric delay); Earth's magnetic field; interference from radio waves and debris from sunbursts in the atmosphere." Again the noisiness of the data caused ambiguity fixing problems. Wrongly fixed ambiguities in a single frequency solution will drastically alter baseline results by up to 10 cm or more. This would be more pronounced in a limited constellation. Sky plots of the six campaigns 1988 to 1994 can be seen in figure 2.1.

The campaign of 1992 saw the first full use of dual frequency receivers. Observations were conducted by Maraven S.A. Shortly after this time the author became involved in the project, visiting the location and becoming involved in the post processing. Three new stations (9201, 9202 and 9203, figure 1.3) known as the benchmark stations were established in an expected stable zone. Unfortunately, in 1992, although three dual frequency receivers were employed, only two of the three receivers in each session were observing the L2 band. This meant that only one of the possible three baselines can be processed in dual frequency mode, which is insufficient for a strong network. Combining one dual and one single frequency line for each session meant that 33 out of 60 independent lines were dual frequency. However, as discussed in chapter five, this proved to be problematic. Single frequency data for 1990, 1991, and 1992 is very noisy.

The 1993 and 1994 campaigns successfully observed the whole network with dual frequency data. These data sets proved far superior to prior campaigns. This in whole was
not due to dual frequency observations，but a significant decrease in the noise level of the data，due to a much less disturbed ionosphere／troposphere．A more detailed analysis of the data quality for 1992 to 1994 is given in chapters five and six．The 1993 and 1994 campaigns were conducted by Maraven and processed by Maraven and UNB．

## TYPICAL SKY DISTRIBUTION OF GPS SATELLITES IN VENEZUELA

Figure 2.1. GPS skyplots 1988-1994.

Since 1988, the six campaigns have not fully covered the entire GPS network, due to yearly expansions and the odd station destruction (see table 2.1). A central core from Tia Juana down to Bachaquero (involving 17 of the 26 stations) has been continually observed throughout this period. Thus this report has focused primarily on these stations only, and the campaigns 1990 to 1994, as the 1988 campaign was of the poorest quality compared to the later surveys.

By 1994 the GPS network covered some $70 \mathrm{~km} * 30 \mathrm{~km} * 100 \mathrm{~m}$, with 26 stations, and involved some 90 baselines ( 60 independent). The lengths of which vary from $2.5-31 \mathrm{~km}$, with elevation differences generally no greater than 60 m .

### 2.2 Test Baselines

In late 1991 and 1992, after the purchase of the newly upgraded receivers, an experiment was carried out by UNB and Maraven to frequently re-observe some baselines, in addition to the yearly campaigns, to analyse the systematic effects over time with a changing constellation. These data sets have been collectively termed the test baselines. GPS data was collected on a monthly to quarterly basis, in a portion of the network between Lagunillas and Bachaquero. Six baselines in the region of Bachaquero were observed for periods of four hours on two consecutive days. These are tabulated in table 2.2. The author processed and analysed the test baseline data from 1992, the results of which are discussed in chapter six.

| Maselliry | length. $(\mathrm{m})_{1}$ | Asimuth (deg) |

## Chapter 3

## GPS Errors and Biases

Information on the GPS is now widely available, in many thorough literature. Some recommended texts are Wells et al [1986], Hofmann-Wellenhof et al [1992], Seeber [1993] and Leick [1994]. This chapter will only discuss the errors and biases in the GPS, which are pertinent to this thesis.

### 3.1 Satellite/Receiver

### 3.1.1 Clock Biases

A synchronised time scale, namely GPS time, is the basis for precise positioning using GPS. The satellite clocks consist of caesium or rubidium oscillators, and are of the highest stability ( $1 * 10^{-11}$ to $1^{*} 10^{-12} \mathrm{sec}$.). However, regular monitoring is still carried out to ensure that each clock stays within $\pm 1 \mathrm{~ms}$ of GPS time [Wells et al, 1986]. Polynomials are produced to describe the drift of each satellite clock, which are then transmitted to the user in the broadcast message. Receiver clocks, which typically utilise quartz oscillators $\left(1 * 10^{-10} \mathrm{sec}.\right)$, can have much larger biases that can be estimated in the post processing. Stability of the receiver clock throughout its observation period is more important than the
accuracy. Strict adherence to GPS time is more important in single point positioning. In relative positioning, differencing of the observations will eliminate most of the errors in both the satellite and receiver clocks. Problems will only arise if different receiver types are utilised, which observe at different epochs.

### 3.1.2 Broadcast Orbits

In the case of this study, broadcast orbits have been utilised in the post processing of the GPS data. The broadcast ephemeris, provided by the GPS Operational Control Segment, is computed from a series of five global tracking and monitor sites. Orbits are computed from the previous seven days, and then extrapolated for the following day(s). Sequential improvements are made to the orbits using the most recently available tracking data. The complexity of modelling all the forces acting on the satellite leads to errors in the computed orbits, which rapidly increase after the given time period of use. Orbital errors are broken down into three components; along track, cross track and radial. Remondi and Hofmann-Wellenhof [1990] compared the broadcast and precise ephemerides produced by the National Geodetic Survey and found "the maximum along track differences to be 5.3, 13.3 and $21 m$ for caesium, rubidium, and quartz clock satellites, respectively." In the case of single point positioning this error will translate directly into the point position error. But in relative positioning some of the error will cancel out. A rule of thumb guideline is given as [Beutler et al, 1984]:

$$
\begin{equation*}
\frac{\delta \mathrm{b}}{\mathrm{~b}}=\frac{\delta \mathrm{r}}{\rho} \tag{3.1}
\end{equation*}
$$

where
$\delta b \quad$ is the baseline error
b is the baseline length $\delta r \quad$ is the orbit error
$\rho \quad$ is the satellite-receiver range

Assuming an ephemeris error of 20 m (say), the baseline error becomes 3 cm for a 30 km baseline (the longest line in the Costa Bolivar GPS network). Chen and Langley [1990a] consider this to be too pessimistic and quote an alternative formula. Wells et al [1986], Beutler et al [1989a], and Spofford [1992] predicted the accuracy of the broadcast ephemeris to be 0.5 ppm , under a full constellation.

### 3.1.3 Multipath

Multipath is defined as one or more reflected signals reaching the antenna, in addition to the direct signal. Two situations are possible; reflection at the satellite and reflection around the antenna. For short baselines, satellite multipath is considered to be the same for both receivers, so will cancel in the observation differencing [Georgiadou and Kleusberg, 1988]. Receiver multipath affects both the carrier phase and code measurements, but by far the greatest effect is on the code. Multipath is site and antenna dependent. A recent test of the new TurboRogue receiver found effects on the C/A and P-code measurements to be 72 cm and 22 cm respectively [Meehan et al, 1992a]. Carrier phase measurement can experience phase shifts up to $90^{\circ}$ of the wavelength, which on $L_{1}$ could result in a 5 cm bias [Georgiadou and Kleusberg, 1988]. New style micro-strip antennas are reported to be almost free of phase multipath effects [Doucet, 1989].

### 3.1.4 Fixed Co-ordinate Bias

In relative GPS, one requires the absolute co-ordinates of one so called fixed point, in the network, from which co-ordinate seeding can take place. In a first campaign situation, these are usually not known, and are obtained from a best pseudorange position from the GPS data or from past Transit/Doppler satellite data if available. Both methods have limitations on the accuracy obtainable. In either case, any bias of the estimated coordinates from the true WGS84 co-ordinates will cause systematic rotations and scale changes of the baseline components. Santerre [1989] demonstrated that a horizontal offset of 10 m would primarily cause a $0 "-0.12$ " vertical rotation of the network, about a horizontal axis perpendicular to the offset. A secondary scale bias of $0-0.5 \mathrm{ppm}$ per 10 m offset could also be expected. For an offset in the height component, the primary effect would be a 0.2 ppm horizontal scale change per 10 m offset.

In the case of deformation studies, it is usual to use the same estimated co-ordinates for the same fixed point(s) in each campaign, depending on the type of datum constraint used. It is then expected that the effect of the bias would be the same from year to year and thus cancel out. The above effect however, was still investigated using the 1992 data set. Results and rotations are shown in section 6.8.3.

### 3.1.5 Selective Availability

Selective availability is the intentional degrading of the GPS accuracy, to non authorised users. It involves two processes, dithering of the satellite clock and degeneration of the
orbital parameters in the broadcast message. Both effects will further bias the pseudorange. In relative positioning, dithering effects can be elliminated through receiver differencing, providing observations are made at identical epochs. However, the errors in the orbital parameters, will only be reduced [Georgiadou and Doucet, 1990].

### 3.2 Atmospheric Effects

### 3.2.1 Ionospheric Effect

The ionosphere is that region of the atmosphere extending approximately 50 km to 1000 km , made up of electrically charged atoms and molecules. High energy photons, in the sun's extreme ultraviolet and x-ray radiation, colliding with the atoms, cause the release of their electrons, resulting in free electrons, and positively charged atoms and molecules, termed ions. Thus this process is known as ionisation. It is the number of free electrons, or more correctly the density, that affect the propagation of radiowaves through this medium. Solar flares, storms and geomagnetic activity enhance the effect.

The electron density is measured as the number of free electrons in a vertical column with a cross sectional area of $1 \mathrm{~m}^{2}$. This number is denoted as the Total Electron Content (TEC). Typical zenith values are $5 * 10^{16}$ to $5 * 10^{17}$ free electrons per $\mathrm{m}^{2}$ [Davidson et al, 1983]. To simplify the number, a base unit has been defined, called the Total Electron Content Unit (TECU) where 1 TECU $=10^{16}$ electrons. TEC along the signal path can be substantially higher, depending on the zenith angle to the satellite.

At night, the free electrons and ions tend to recombine, reducing TEC, thus a strong diurnal variation occurs. The diurnal variation in most areas follows a general trend, whereby the value of TEC peaks around 1400 hr , local time, until approximately 2000 hr , before decreasing overnight. Much shorter and longer term periods of TEC variation also occur. Short term variations of approximately 10 minutes can be caused by wave like disruptions in the upper neutral atmosphere, from severe weather fronts and volcanic activity. These are denoted as Travelling Ionospheric Disturbances (TID). Longer term periods of 27 days, coinciding with rotation of the sun, are caused by high speed solar wind streams containing high energy particles spuen from the coronal holes. Seasonal periods, coinciding with the spring and vernal equinoxes also occur, and are linked to the changing elevation angle of the sun. A much stronger variation occurs on an 11 year period, and is linked to the solar sunspot cycle. The most recent peak (cycle \#22) occurred between 1989 and 1992 (figure 5.1). It can be seen that the time period from minimum to maximum, is shorter than from maximum to minimum, and thus some additional disturbances can be expected a few years after the maximum.

Spatial variations of TEC also occur, which pose more of a problem to relative GPS positioning. Generally TEC values are highest in the equatorial regions and decrease towards the poles. Spatial variations of TEC cause horizontal gradients in both the N/S and E/W directions. N/S gradients tend to be worse than E/W. Low elevation satellites on opposite sides of the horizon can have sub-ionospheric points separated by some 3000 km [Klobuchar, 1990]. It is unlikely that the satellite paths would undergo similar ionospheric
effects, thus observation differencing would not eliminate the problem. Dual frequency processing can use certain linear combinations to reduce the effect, but single frequency users could expect scale biases of up to 30ppm, in the baseline length [Wanninger, 1993].

Ionospheric studies in the equatorial and polar regions have revealed further short term effects, known as scintilations. These scintilations or small scale irregularities cause both refraction and diffraction of the GPS signal [Wanninger, 1993]. Three distinct bands are defined (figure 3.1). Scintilations mainly occur in the equatorial anomaly, which is a band stretching $\pm 15^{\circ}$ either side of the geomagnetic equator. Studies by Wanninger and Campos [1991,1992], have shown there to be a distinctive diurnal variation, with maximum scintilations effects occurring between sunset and midnight, and sometimes lasting well into the morning. These effects are often higher than the first such maximum, experienced after noon, local time. Seasonal variations with respect to longitude also occur. The region between the Americas and India suffer worst effects between September and March, with little chance of effects between April and August. The situation is reversed for the Pacific region. A strong correlation with the 11 year solar sunspot cycle is also evident. The polar regions also experience scintilation effects, but generally only at night and at certain times of the year, and are not as pronounced as equatorial regions. Mid latitudes are generally free of such effects, however in times of high scintilation activity, the auroral and equatorial regions have been known to extend into the usual mid latitudes.

Refraction causes curvature of the ray path and propagation of the signal velocity. Diffraction causes both signal fading and enhancements, commonly known as amplitude scintilations. Severe amplitude scintilations can result in loss of lock of the signal, depending on key factors such as receiver bandwidth and type of tracking channel. Squaring receivers have a $\mathrm{S} / \mathrm{N}$ ratio 30 db lower than direct code-correlation [Leick,1994], and are more likely to suffer from data loss and cycle slips. Amplitude scintilations can be examined by plotting receiver $\mathrm{S} / \mathrm{N}$ ratios for each satellite at each epoch. Signal to noise ratios vary with satellite elevation, and scintilations would appear as spikes in this arc.

Figure 3.1. Major geographic areas of the Ionosphere [after Bishop et al, 1991].

Phase scintilations result from both refraction and diffraction, causing shifts in the phase by up to several cycles between two epochs. This complicates data processing as such a phase shift may appear as a cycle slip. Rapid phase scintilations can cause phase changes
beyond the bandwidth of the receiver, again resulting in loss of lock. Phase scintilations can be examined from single station dual frequency data. Relative ionospheric delay and rate of change (ROC) of the delay can be calculated from a combination of the code and carrier observables. Effects would show up as spikes in the ROC plots (cf. chapter five).

### 3.2.1.1 Ionospheric Effects on GPS Code and Carrier.

Refraction of the GPS signal in its travel through this medium is proportional to the density of free electrons along the signal path. The GPS signal consisting of the carrier phase, a pure sinusoid and the modulated carrier (code), an amalgamation of many pure sinusoids, is affected in different ways [Klobuchar, 1990].

According to Seeber [1993] the refraction coefficient for carrier signals is defined as:

$$
\begin{equation*}
\mathrm{n}_{\mathrm{p}}=1+\frac{\mathrm{C}_{2}}{\mathrm{f}^{2}}+\frac{\mathrm{C}_{3}}{\mathrm{f}^{2}}+\frac{\mathrm{C}_{4}}{\mathrm{f}^{2}}+\ldots . \tag{3.2}
\end{equation*}
$$

Where $\mathrm{C}_{2}$ is defined as $-40.3 \mathrm{n}_{\mathrm{e}}$, f the frequency, and $\mathrm{n}_{\mathrm{e}}$ is the local electron density $\left(\mathrm{e} / \mathrm{m}^{3}\right)$. Neglecting higher order terms, the refraction index of the carrier phase becomes:

$$
\begin{equation*}
\mathrm{n}_{\mathrm{p}}=1-\frac{40.3}{\mathrm{f}^{2}} \mathrm{n}_{\mathrm{c}} \tag{3.3}
\end{equation*}
$$

Similarly, for the code, a refraction coefficient is defined as:

$$
\begin{equation*}
\mathrm{n}_{\mathrm{g}}=1-\frac{\mathrm{C}_{2}}{\mathrm{f}^{2}}-\frac{2 \mathrm{C}_{3}}{\mathrm{f}^{2}}-\frac{3 \mathrm{C}_{4}}{\mathrm{f}^{2}}-\ldots . \tag{3.4}
\end{equation*}
$$

Which, after neglecting the higher order terms, becomes:

$$
\begin{equation*}
\mathrm{n}_{\mathrm{g}}=1+\frac{40.3}{\mathrm{f}^{2}} \mathrm{n}_{\mathrm{e}} \tag{3.5}
\end{equation*}
$$

Integration of the refractive index along the signal path will provide the effect of the ionosphere, after accounting for the geometric distance, giving [Davidson et al, 1983]:

$$
\begin{align*}
& \delta \rho_{\text {ion }}=\int_{\text {SAT }}^{\text {REC }}\left(n_{\mathrm{g}}-1\right) \mathrm{ds}  \tag{3.6}\\
& \delta \rho_{\text {ion }}=\frac{40.3 \mathrm{TEC}}{\mathrm{f}^{2}} \quad \text { (metres) } \tag{3.7}
\end{align*}
$$

Typical values can vary from 50 m in the zenith to 150 m on the horizon [Wells et al,1986]. The effect on the phase is of roughly the same magnitude, with opposite sign, in cycles.

### 3.2.2 Tropospheric Effect.

The troposphere is one part of the so called neutral atmosphere, where no ionisation occurs, which extends up to about 40 km . The troposphere itself is the first layer extending from the ground to $9-16 \mathrm{~km}$, depending on the latitude. Unlike the ionosphere, the troposphere is not dispersive for microwave frequencies, thus the propagation effect on the carrier phase and modulation is the same, and is not frequency dependent. Thus an elimination of the effect through linear combinations of the two signal frequencies is not possible.

The propagation of signals through this medium depends on the temperature, pressure and water vapour content. Temperature and pressure gradients tend to vary gradually over space and time, but water vapour content can be widely varied. Measurements of the temperature and pressure can be easily made at the receiver site, but these figures do not really correlate to the conditions along the signal path. Observations of water vapour content require expensive and bulky equipment. Thus modelling of the refractive index of the troposphere can be awkward. Integration of the refractive index along the signal path will yield the effect on the range. The refractivity can be broken into two unequal parts; a dry component, making up about $90 \%$, and a wet component, the remainder. Integration of the refractivity along the signal path is complicated. One such formula, derived by Hopfield [1971] and modified by Seeber [1993] is as follows:

$$
\begin{aligned}
& \delta \rho_{\text {trop }}=\frac{\mathrm{K}_{\mathrm{d}}}{\sin \left(\mathrm{E}^{2}+6.25\right)^{0.5}}+\frac{\mathrm{K}_{\mathrm{w}}}{\sin \left(\mathrm{E}^{2}+2.25\right)^{0.5}} \\
& \mathrm{~K}_{\mathrm{d}}=155.2 * 10^{-7} \frac{\mathrm{P}}{\mathrm{~T}} \mathrm{H}_{\mathrm{d}} \\
& \mathrm{~K}_{\mathrm{w}}=155.2 * 10^{-7} \frac{4810 \mathrm{e}}{\mathrm{~T}^{2}} \mathrm{H}_{\mathrm{w}}
\end{aligned}
$$

where
\(\left.$$
\begin{array}{ll}\mathrm{K}_{\mathrm{d}}, \mathrm{K}_{\mathrm{w}} & \text { describe the dry and wet components } \\
\text { E } & \text { satellite elevation in degrees } \\
\text { P } & \begin{array}{l}\text { air pressure, in Hectopascal (HPa) } \\
\text { T }\end{array}
$$ <br>

temperature, in degrees Kelvin\end{array}\right]\)| partial pressure of the water vapour, in Hectopascal |
| :--- |
| $\mathrm{H}_{\mathrm{d}}, \mathrm{H}_{\mathrm{w}}$ |$\quad$| are the effective altitudes of the dry and wet terms |
| :--- |

The zenith tropospheric delay is very susceptible to small changes in the meteorological values, which cause changes in the baseline height component. These effects are greatly magnified for lower elevation satellites. Beutler et al [1989b] quote that a one degree error in the relative temperatures of the baseline ends, can cause a bias of $10-80 \mathrm{~mm}$, in the height component. The climate in this region is such that high temperatures and relative humidity are experienced all year, which are fairly stable.

### 3.3 Carrier Beat Phase Ambiguity and Cycle Slips

Until such time, as the code observable becomes accurate enough to well within half a cycle of the carrier phase, the question of carrier phase ambiguity will remain. The search for the true ambiguity and fixing it to its integer value is key to precise baseline determination, especially in small to medium networks [Wubbena, 1988]. This process is made easier when a variety of data types are available. Hofmann-Wellenhof et al [1992] quote three strategies, and give an in-depth derivation. Single frequency ambiguity resolution is the hardest, as the ambiguity value is biased by the effects of the atmosphere and orbit errors. Observation differencing alleviates the problem to some extent. The use of dual frequency data eases the problem more, by allowing different linear combinations of the L1 and L2 observables to be made, resulting in a larger (or smaller) wavelength, which can be more easily resolved. The so called wide and narrow lane techniques are well discussed [Blewitt, 1989]. However, there is often a trade off between better ambiguity resolution, observation noise, error suppression, and whether or not the ambiguity is integer in nature. Bruyninx [1994] summarises the advantages of different
combinations. A combination of dual frequency code and carrier data can be made to eliminate the effects of biases (including the ionosphere), providing an observable with an integer ambiguity and a long wavelength (cf. section 4.3).

Cycle slips or loss of lock on the signal, further complicate the problem. If lock is maintained on other satellites, or enough data has been acquired prior to the slip, they often can be easily repaired. Failing repair, a new ambiguity has to be computed, weakening the baseline quality. Further complications arise when jumps in the phase occur, due to the rapid effects of ionospheric activity that exceed the phase wavelength. Such jumps may become confused as cycle slips and be corrected as such.

### 3.4 Residual Effects

A few smaller biases and errors are also present in the system, which contribute to the overall noise level of the results. These include hardware biases in both the satellite and receiver, observation noise and antenna phase centre variations. Current technology dictates the level of hardware biases, or electrical delays in the satellite or receivers circuitry. Seeber [1993] quotes receiver biases to be about 2.5 mm . Observation noise is dependent on the signal to noise ratio of the satellite signal, type of receiver tracking channel and the receiver bandwidth. The general rule of thumb guideline is that observation resolution is $1 \%$ of the wavelength [Wells et al, 1986]. However, current digital receiver technology has advanced this to about 1.5 cm for the P -code, and 1.3 mm for the L1 carrier phase [Meehan et al, 1992b]. Antenna phase centre variations are less
common in modern antennas. Using the same antenna type, variations are less than 5 mm , but variations up to a few centimetres can be expected if different antenna types are mixed in one campaign [Geiger, 1990].

### 3.5 Anti-Spoofing

Anti-spoofing (AS), although not a bias, is a current problem and concern for geodetic surveyors. AS or encryption of the P-code, basically denies unauthorised users access to the Precise Positioning Service (PPS). Up until now, current GPS work in geodetic surveying has made maximum use of the P-code, enabling many ambiguity resolution techniques and optimal ionospheric removal. Different receiver types handle AS in various different ways, recovering some aspects of the P-code.

## Chapter 4

## GPS Processing

This chapter outlines the GPS software used in the processing of the data; some reasons for choosing the software; the processing procedures and the different solution types employed.

### 4.1 Software Selection

The selection of "which software to use" was made for a number of reasons. Firstly, most of the campaigns have been observed with Trimble receivers, and two have already been processed (namely 1990 and 1991) by Usher Canada Ltd. and Coler and Colantonio Inc. [1990] and Coler and Colantonio Inc. [1991], using the Trimble Trimvec Plus software [Trimble, 1992]. Secondly, the Trimvec Plus software is also currently being used by Maraven for processing. Such commercial processors are fairly automated in their approach to GPS baseline processing, and thus lend themselves to cost cutting of the survey. At present, it seems only fitting that this processor be a part of the analysis. Unfortunately, Trimvec Plus lacks the ability to allow the user to view the least squares residuals of the Double Difference processing. This is an important part of any GPS survey, as they can reveal the solution quality, show systematic trends and ensure
complete cycle slip fixing. Thus a second processor was chosen to process the 1992 and 1993 campaigns, which had this feature. Due to familiarity and ease of use, the Ashtech Geodetic Post Processing Software (GPPS) was chosen [Ashtech, 1993]. This would also provide an interesting comparison between two so called Black Box commercial processors. In the case of the Trimvec Plus software, a number of different processors are available. The author chose to use the Trimvec Multi Baseline Processor (TRIMMBP) of the Trimvec Plus software (version E). The Ashtech software was GPPS (version 4.50).

It is realised that for a complete study, the use of a more sophisticated software such as UNB's Differential Post Processor (DIPOP) [Chen and Langley, 1990b] would be very beneficial in revealing any problems or systematic trends or biases that may be inherent in the commercial software. Unfortunately, this was considered beyond the scope of the thesis, to process a whole campaign with a third processor. However a brief comparison of the two commercial processors and DIPOP was made on a separate smaller data set, from a network observed for the Superconducting Super Collider project in Texas, and is discussed later in section 4.5.

### 4.2 Software Comparison

Both commercial software packages operate on a similar format, aiming for optimum user friendliness by providing a fully automated system, in which the elimination of noisy/bad data, detection and treatment of cycle slips, and ambiguity resolution, are all handled within the software. A user more familiar with such questions, can select manual
processing mode, to tweak the results, but still has little influence on the end results. Little is published about the algorithms and criteria used to answer these questions. Thus, an assessment of performance and compatibility mainly relies on a comparison of output files. This would involve comparing baseline components for both float and fixed Double Difference solutions, rms of the residuals, ambiguity ratio factors, percentage of rejected data, loop misclosures and residual plots (if available) of the single baseline solutions. In a network of independent baselines, final adjusted co-ordinates, magnitude and distribution of residuals can be compared. A posterior variance factors will assess the quality of the GPS processor weights, which in general are over optimistic.

Generally, the two software work on a similar basis. The main difference lies within the interface. GPPS uses a step by step interactive screen approach, whereas TRIMMBP utilises a command line approach. The only significant limitations between the software are that GPPS does not allow the user to delete portions of one satellite data, but only the whole satellite, or the whole portion of all the satellites, which can be quite drastic. TRIMMBP lacks the capability to view the Double Difference residuals, and does not allow the user to select the reference satellite. GPPS will only carry out single baseline processing, whereas TRIMMBP can handle both single baseline and session processing.

### 4.3 Solution Types

In addition to L1 and L2 single frequency processing, both software offer combined frequency processing to eliminate the ionospheric effect and provide stronger ambiguity
resolution. The first combination, denoted L3, is the so called Ionospheric Free Combination [Ashtech, 1993].

$$
\begin{equation*}
\mathrm{L} 3=\mathrm{L} 1-\left(\mathrm{f}_{\mathrm{L} 2} / \mathrm{f}_{\mathrm{L} 1}\right) \mathrm{L} 2 \tag{4.1}
\end{equation*}
$$

By nature, the L3 solution removes almost all of the ionospheric effect, but is limited to float ambiguities and can be up to three times noisier than L1 only. A fixed ambiguity combination can be made via the Wide-Lane technique discussed by Blewitt [1989]. The combination is seen in the following equations [Talbot, 1992]:

$$
\begin{equation*}
\mathrm{L}_{\mathrm{wL}}=\left[\left(\mathrm{L}_{1} / \lambda_{\mathrm{L} 1}\right)-\left(\mathrm{L}_{2} / \lambda_{\mathrm{L} 2}\right)\right] \lambda_{\mathrm{wL}} \tag{4.2}
\end{equation*}
$$

where $\quad \mathrm{L}_{\mathrm{wL}} \quad$ is the wide-lane phase measurement
$\lambda_{\mathrm{L} 1}, \lambda_{\mathrm{L} 2}, \lambda_{\mathrm{WL}}$ are the corresponding wavelengths

According to Trimble [1992], this combination will eliminate most of the ionospheric effect. This analysis found this not to be the case. According to Wubbena [1989], the wide-lane combination contains an ionospheric bias similar to that on L1 or L2 only. This combination has been denoted by L 0 in the rest of the thesis.

GPPS offers a slight variation on the above two techniques, in order to achieve an integer ambiguity combination with a reduced ionospheric effect. Termed the Wide-Lane Ionospheric Free solution, it is seen in the following equations [Ashtech, 1993]:

$$
\begin{array}{lll}
\mathrm{N}_{\mathrm{WL}}=\mathrm{N}_{1}+\mathrm{N}_{2} & \text { or } \quad \mathrm{N}_{2}=\mathrm{N}_{1}-\mathrm{N}_{\mathrm{WL}}  \tag{4.3}\\
\mathrm{~N}_{3}=\mathrm{N}_{1}+\mathrm{AN}_{2} & &
\end{array}
$$

where A is a frequency ratio for ionospheric removal $\mathrm{N}_{1}, \mathrm{~N}_{2}, \mathrm{~N}_{\mathrm{WL}}$ are the corresponding ambiguities

$$
\begin{equation*}
\mathrm{N}_{3}=\mathrm{N}_{1}+\mathrm{A}\left(\mathrm{~N}_{1}-\mathrm{N}_{\mathrm{WL}}\right) \tag{4.4}
\end{equation*}
$$

Once the wide lane bias ( $N_{W L}$ ) is fixed, then the L1 bias can be fixed through the ionospheric-free combination. This combination is also denoted by L0 in the thesis. The author wishes to point out that any future reference to a TRIMMBP L0 solution will imply the Wide-Lane combination, whereas a GPPS L0 solution will imply the Wide-Lane Ionospheric Free combination.

The newest release of the TRIMMBP software (called GPS Survey), now offers another combination to tackle this problem. The combination is a Wide/Narrow Lane solution, whereby the wide-lane phase measurement is combined with the narrow-lane code measurement, to obtain a strong estimate of the wide-lane ambiguity. This ambiguity is free of atmospheric, ephemeris, satellite clock and receiver clock errors. It is shown in the following equations [Talbot, 1992]:

$$
\begin{align*}
& \mathrm{L}_{\mathrm{wL}}=\left[\left(\mathrm{L} 1 / \lambda_{\mathrm{L} 1}\right)-\left(\mathrm{L} 2 / \lambda_{\mathrm{L} 2}\right)\right] \lambda_{\mathrm{wL}}  \tag{4.5}\\
& \mathrm{P}_{\mathrm{NL}}=\left[\left(\mathrm{P} 1 / \lambda_{\mathrm{L} 1}\right)+\left(\mathrm{P} 2 / \lambda_{\mathrm{L} 2}\right)\right] \lambda_{\mathrm{NL}} \tag{4.6}
\end{align*}
$$

where $\quad \mathrm{P}_{\mathrm{sL}} \quad$ is the narrow-lane code measurement $\mathrm{P} 1, \mathrm{P} 2$ are the L 1 and $\mathrm{L} 2, \mathrm{P}$-code measurements

By equating the wide-lane phase measurement and the narrow-lane code measurement, a direct estimate of the wide-lane phase ambiguity can be found, as follows [Talbot, 1992]:

$$
\begin{equation*}
\mathrm{N}_{\mathrm{WL}}=\left(\mathrm{P}_{\mathrm{NL}}+\mathrm{L}_{\mathrm{wL}}\right) / \lambda_{\mathrm{wL}} \tag{4.7}
\end{equation*}
$$

The tropospheric effect is estimated using the Modified Hopfield model in TRIMMBP and the Hopfield model in GPPS.

### 4.4 Data Processing

As mentioned earlier, the GPS campaigns 1990; 1991; 1993 and 1994 were also processed by a third party. Results and conclusions for these campaigns are contained in Usher Canada Ltd. and Coler and Colantonio Inc. [1990], Coler and Colantonio Inc. [1991], and Congecca [1993,1994]. Final adjusted co-ordinates for these years are tabulated in Appendix B. The author processed data from 1992, 1993 and 1994 in both TRIMMBP and GPPS using a variety of solution types. These are tabulated in table 4.1. The two TRIMMBP L0 solutions were provided by Maraven S.A.

| Year | Suflume | Temmane |
| :---: | :---: | :---: |
| 1992 | Trimble TRIMMBP | L1 |
| 1992 | Ashtech GPPS | L1 |
| 1992 | Trimble TRIMMBP | L0 (all available) |
| 1993 | Ashtech GPPS | L1 |
| 1993 | Ashtech GPPS | L3 |
| 1993 | Trimble TRIMMBP | L0 |
| 1994 | Trimble TRIMMBP | L0 |
| 1994 | Ashtech GPPS | L3 |

Table 4.1. Software employed between 1992 and 1994.

In table 4.1, the column containing technique relates to the processing technique employed. Where L1 is the "single frequency L1" solution, L3 is the "Ionospheric Free Combination" and L0 is the "Wide-Lane Combination".

Processing procedures were similar for both software. Baselines were processed in a single baseline solution fashion, as opposed to a session solution. Run time parameters were as follows:

## TRIMMBP :

: Station 0202 fixed
Latitude: N $10^{\circ} 12^{\prime} 31.80970^{\prime \prime}$
Longitude: W 71 ${ }^{\circ} 9^{\prime} 11.65150{ }^{\prime \prime}$
Height: $\quad 53.773 \mathrm{~m}$
: Broadcast Ephemeris (Hourly)
: Elevation Mask $=15^{\circ}$
: Default Meteorological Values;
Temperature : $\quad 20^{\circ} \mathrm{C}$
Pressure : $\quad 1013 \mathrm{mb}$
Humidity: $\quad 50 \%$
: Modified Hopfield Tropospheric model
: No Ionospheric modelling

## GPPS :

: Station 0202 fixed
Latitude: $\quad \mathrm{N} 10^{\circ} 12^{\prime} 31.80970{ }^{\prime \prime}$

Co-ordinates for the fixed point (station 0202) were computed from the pseudorange data observed in 1988. Their worth was questionable. New co-ordinates were made available during December 1993. For consistency, the old co-ordinates have been used in the processing of all the campaigns. The new co-ordinates were obtained from a nearby Transit Doppler Station, observed in 1985 by the University of Zulia in conjunction with the University of Hannover. Station 0202 was tied to the Doppler station with the GPS in 1993. The Doppler station is located some kilometres south of Bachaquero, and is beyond
the subsidence zone. The new values disagree with old co-ordinates by 15 m in latitude, 3 m in longitude and 2 m in the height.

Considering the flatness of the network terrain and the stability of the climate, the default surface meteorological values have been used in each software. Trimble [1992] highly recommend using this method, for short baselines with a small height difference ( $<300 \mathrm{~m}$ ).

For some unknown reason, the two software use slightly different standard meteorological values. Temperature and humidity are equivalent, but pressure is different by 3 mb . This is worrying considering the susceptibility of the tropospheric models to the slightest change in atmospheric conditions (cf. section 3.2.2).

In the processing of the 1992 data, it was found that much improved results were obtained when using a cut off angle of $20^{\circ}$ as opposed to the normal $15^{\circ}$ used in the later campaigns. This was true for both software. Better integer search ratios; rms of the residuals and day to day repeatability were achieved under this setting. This was also true of the 1991 campaign [Coler and Colantonio Inc., 1991]. The 1993 and 1994 campaigns used a $15^{\circ}$ elevation mask.

### 4.5 Test Comparison to DIPOP

In order to gain some insight into the commercial software, a comparison was made with DIPOP, using a small data set from the aforementioned Texas network, utilising DIPOP as
a benchmark. The data set obtained with Ashtech LXII receivers consists of three baselines, ranging from $18-28 \mathrm{~km}$ in length. Full wavelength dual frequency P-code data was observed in two sessions of four hours. All data was processed in both software in three modes L1, L3 and L0. One L3 solution for each baseline was obtained from the DIPOP processor [Komjathy, 1993].

In total, seven solutions were obtained for each baseline (table E1, appendix E). Average rms of the residuals was 16 mm for GPPS and 17 mm for TRIMMBP. GPPS was consistently around 16 mm for all solution types. However TRIMMBP varied a great deal from 5 mm to 45 mm . The results between GPPS and DIPOP generally agree very well. TRIMMBP did not agree so well, as six of the eighteen solutions appear as outliers; three in L3, two in L1 and one in L0. In the L1 and L0 solutions, the software had problems fixing the ambiguities and rms of the residuals were high. Most of the outliers seem to be weakest in the dx baseline component, compared to DIPOP and GPPS, which in Texas corresponds to the longitudinal component. Four of the six outliers are the longer, 28 km , baselines.

Internal and external 3D loop misclosures were calculated for each session and solution. These are tabulated in tables E2 to E8, in appendix E. The DIPOP 3D loop misclosures were good both internally and externally, varying between 14 mm and 49 mm . This translates to better than 1 ppm of the sum of the three distances (approx. 70km). The GPPS loop closures were generally equally good, varying between 7 mm and 75 mm , still
within 1 ppm . With six outliers, the TRIMMBP closures are not so consistent, ranging from 9 mm to 856 mm , i.e. $1-12 \mathrm{ppm}$. Three of the six L0 and L 1 external loop misclosures were around 1 ppm . All six L3 closures were poor. Such high misclosures could be expected in areas of high ionospheric activity, using L1 solutions, where biases of 510 ppm can occur. However, three of the six outliers were L3 ionospheric free solutions, and QC (cf. section 5.1) analysis of the data showed ionospheric activity to be low.

DIPOP performed well from day to day, giving a repeatability of 1 ppm of the baseline length (figure 4.1). All three GPPS solutions also had good repeatability. The largest difference was one L3 solution at 2ppm. Trimvec, because of the outliers, had much worse repeatability. Four of the nine solutions were within 2 ppm , three varied between $4-7 \mathrm{ppm}$, and two were blunders.

Using DIPOP as a benchmark, all solutions were differenced with the DIPOP L3 solution (figures 4.2 and 4.3). All eighteen GPPS solutions were within 2 ppm . Interestingly enough, all the middle length baselines ( 23 km ) agreed within 0.5 ppm of DIPOP, in all six solutions. Twelve of the eighteen Trimvec solutions were within 2 ppm of DIPOP. Four differed by up to 6 ppm , and the remaining two were obvious blunders. No correlation between baseline length or solution type, could be made with the weak solutions.

In general, the Ashtech software handled it's own data very well, and no processing problems were encountered. Trimble software had a few problems in six of the eighteen solutions, but otherwise agreed reasonably well with DIPOP.

## Chapter 5

## GPS Data Assessment

A brief assessment of the data quality for the campaigns 1991 to 1994 has been made using the program Quality Check available from UNAVCO, Colorado [UNAVCO, 1993].

### 5.1 Quality Check (QC)

According to the QC documentation [UNAVCO, 1993], "The QC program forms linear combinations of the GPS range and carrier phase data to compute (1) L1 pseudorange multipath for the C/A or P-code observations, (2) L2 pseudorange multipath for $P$-code observations, (3) ionospheric phase effects on the L1 carrier frequency and (4) the rate of change of the ionospheric delay". The author's main interest in using the program was to evaluate the ionospheric effects (3) and (4), at each station, for each of the last four campaigns. The ionospheric delay is derived from the difference of the L1 and L2 carrier phase equations. Unfortunately, it is not possible to estimate the absolute delay for each signal at lock onto the satellite. Thus, the delay itself is expressed relative, to the first observation epoch, where the delay is assumed to be zero. The program requires dual frequency C/A or P-code data from a single station. Thus a full assessment of the 1990
and 1991 campaigns could not be made. However a limited amount of L2 data was available from the August 1991 data set.

### 5.2 Ionospheric Assessment

Although the August 1991 data set was not incorporated in the deformation study, it did provide the author with dual frequency P-code data with which to analyse using QC. For the sixteen available baselines, QC revealed that the relative ionospheric delay consistently reached 20 m after 2 hours, with some peaks up to 30 m . The rate of change (ROC) of the delay was also high, on average $80 \mathrm{~cm} / \mathrm{min}$ with peaks up to $120 \mathrm{~cm} / \mathrm{min}$. The noise level of the 1992 data varied greatly throughout the campaign. The relative ionospheric delay on the L 1 signal ranged from 8 m to 20 m , over 2 hours, with peaks up to 30 m , on some days. The ROC was again high, on average $100 \mathrm{~cm} / \mathrm{min}$, with peaks of $150 \mathrm{~cm} / \mathrm{min}$. However, disturbances in the 1993 data were much less, and the data much smoother. Relative ionospheric delay was on average 2 m over 2 hrs , with peaks of 4 m . The ROC was on average $20 \mathrm{~cm} / \mathrm{min}$. On the whole, the effect was an order of magnitude less. This was also true of the 1994 data which was affected much the same as the 1993 data. In the 1991 and 1992 data sets, although the values were fairly high on many days, the delay and ROC were both fairly smooth, i.e. no scintilation type effects were seen.

### 5.3 Causes of Noisy Data

The high levels of ionospheric delay during 1991 and 1992 data can be attributed to solar sunspot activity. Solar storms and flares directly affect the total electron content in the atmosphere, which in turn delays the travelling signals in a frequency dependent way. According to Blewitt [1989] maximum ionospheric delays occur at the peak of the 11 year solar sunspot cycle, 1989 being the last peak (figure 5.1). The annual maximum is during the spring and vernal equinox, and the diurnal maximum at 1400 hr local time. Tropical regions such as Lake Maracaibo are worst affected. Observation times for each campaign are tabulated in the following table 5.1.

| Yそ̌\% | OM\%』 | IImemal Day (Io cal mime) | Myage session Ienghtifours) |
| :---: | :---: | :---: | :---: |
| 1990 | 115-124 | 2100-0800 | 3 |
| 1991 | $\begin{aligned} & 36-50 \\ & 77-80 \end{aligned}$ | $\begin{aligned} & 1100-2300 \\ & 0800-1200 \end{aligned}$ | $\begin{aligned} & 2 \\ & 2 \end{aligned}$ |
| 1992 | 119-141 | 1700-2200 | 2 |
| 1993 | 214-230 | 0800-1400 | 2 |
| 1994 | 110-119 | 0200-0700 | 2 |

## Table 5.1. Observation dates and times.

Three of the campaigns 1990, 1992, and 1994, were conducted at a similar time during the year (around April/May), i.e. one month after the spring equinox. Daily observation times for each campaign were all between early evening and early next morning. Campaign 1991 was conducted one month prior to and around the spring equinox, with daily observation times throughout noon to midnight. However, the 1991 data examined under QC was taken during August, with observation times from 10-16hr (local time). The 1993
campaign was also conducted in August with observation times from late morning to early afternoon.

Unfortunately, no direct correlation of noisy data and observation time could be made, on a diurnal or seasonal basis, in any of the campaigns. The only apparent trend is the greater noise level of the earlier campaigns 1990 to 1992 . This would signify the possible tailing off of the 11 year solar cycle, which was the case in cycle 22 (figure 5.1).

Figure 5.1. Smoothed monthly sunspot numbers [Komjathy, 1995].

During 1991 and 1992, an international joint project under the heading BRASION (BRASil IONosfera) studied the ionospheric effect on the GPS in Brazil. Wanninger and Campos [1991] reported that in the July 1991 campaign, no scintilations were seen but strong ionospheric effects were observed on even short 10 km lines, concluding that the effects could be expected for some years before and after sunspot maximum. The second
campaign [Wanninger and Campos, 1992] conducted in March 1992, suffered both scintilations and strong ionospheric effects. Long hours of data, more sophisticated post processing software, and access to the $\mathrm{S} / \mathrm{N}$ ratios from the receiver, allowed for a detailed study of the ionospheric effect. Overall, in 1992, they reported that co-ordinate shifts of 530 ppm were experienced, with different data sets. The author suspects that the Venezuela 1991 and 1992 campaigns which were carried out at similar times, and also lying within the equatorial anomaly, may have suffered similar effects.

Unfortunately, at this point in time it is unsure to what extent the ionosphere is causing problems. Other sources of error such as the troposphere and multipath could also be contributing. Westrop [1991] attempted to better model the tropospheric delay but could not find a model or technique that performed satisfactory. As mentioned in section 4.4, a higher elevation mask of $20^{\circ}$ produced better results in 1991 and 1992. This may signify that the tropospheric delay is fairly pronounced, or being handled incorrectly. Tropospheric models based on the Hopfield model tend to over estimate the delay at lower elevation angles, from $20^{\circ}$ and down [Janes et al, 1990].

The accuracy of the orbits will also play a role. As mentioned in section 3.1.2, the accuracy of the broadcast orbits used in this study are expected to be about 0.5 ppm . Noisy data in 1992 created inconsistencies up to ten times this value in the baseline results. Thus the use of the broadcast ephemeris was not considered a limiting factor at this stage. Westrop [1991] demonstrated using a few of the 1990 baselines, that differences in the baseline components were between 0.1-1.3ppm, when using the precise ephemeris.

## Chapter 6

GPS Results (1992-1994)

This chapter looks at the baseline solutions from the campaigns 1992 to 1994, and the 1992 test baselines, processed in TRIMMBP and GPPS, examining the repeatability, double difference residual plots, and the height misclosures. This is followed by the post adjustment analysis, an evaluation through MINQE, and a look at the systematic biases that resulted.

### 6.1 Baseline Processing Using TRIMMBP and GPPS

The author processed data from the campaigns 1992 to 1994. Results from these years using different solution types can be found in appendix A . Tables for all campaigns contain the baseline components ( $\Delta \varphi, \Delta \lambda$ and $\Delta \mathrm{h})$ for each session, together with the rms of the residuals, type of solution ( $1=\mathrm{L} 1,3=\mathrm{L} 3,0=\mathrm{L} 0$ ) and the integer search ratio (ISR). Note that the rms of the residual and integer search ratio have different units in each software. TRIMMBP states that an rms between $0.02-0.09$ cycles, for a baseline up to 20 km , denotes a good solution [Trimble, 1992]. GPPS rms is given in metres. ISR for TRIMMBP greater than 3.0 denotes a strong solution. GPPS ISR between 95 and 100 indicate all ambiguities were fixed well [Ashtech, 1993].

Of all the campaigns processed by the author, 1992 proved the most problematic. Data was generally very noisy. This was seen through weak L1 solutions and poor day to day repeatability in both the TRIMMBP and GPPS software. Noisy data made ambiguity fixing hard, even on very short ( 7 km ) baselines. Solutions between processors differed greatly depending on whether one or both solutions appeared strong. If the rms of the residual was low and the ISR strong, then there was good agreement between the two software at sub-centimetre level. However, if one solution appeared weak, then some very large differences would occur at the deci-metre level, reaching 500 mm in one case. This was true for both baseline length and elevation difference. Average differences in the latitude (phi), longitude (lambda) and height baseline components, between the software, are given in table 6.1. Average differences were calculated using all available solutions. Oddly enough, in all solution types, the longitude component is weaker than the height component. A noticeable improvement in all differences is seen from 1992 to 1994.

Generally the rms for the 1992 TRIMMBP L1 solutions was $0.04-0.08$ cycles ( $8-16 \mathrm{~mm}$ ) denoting a good solution. Often only one baseline from each session had a poor rms (up to 0.2 cycles, or 40 mm ), and these did not agree well with GPPS. The average rms of the GPPS L1 solutions was slightly higher ( $10-25 \mathrm{~mm}$ ), with occasional baselines reaching 50 mm . Weak solutions were not generally confined to the longer baselines. This would suggest a distance independent effect causing the noisy data, such as the troposphere.

Overall the noisiness of the data meant for weak float ambiguity solutions in both software, resulting in some wrongly fixed ambiguity solutions, creating some large differences in the baseline components. Generally fixed ambiguity solutions between the two software agreed slightly better than the float solutions (figures 6.1 and 6.2). Differences were not baseline length dependent.

In 1993, cross-correlated P-code data was observed. Three solution types were produced; L1, L3 and L0. This data set proved fairly clean and smooth, and all solutions agreed much better between processor and solution type. Baseline lengths between TRIMMBP L0 and GPPS L3 generally varied by $0-50 \mathrm{~mm}$, with the odd difference up to 163 mm . The mean difference was 37 mm (figures 6.3 and 6.4). There was a distinct bias between these two solutions, and a non zero mean can be seen in figure 6.3, denoting generally longer baselines from L0. This bias was not seen in 1992, with the L1 solutions, and is not so prevalent in the 1994 solutions (figure 6.4). Elevation differences generally agreed much better, with an average difference of 24 mm .

Figure 6.4. 1994 data set. Baseline length differences.
GPPS L3 - TRIMMBP L0

During January 1994, the US Department of Defence permanently activated AntiSpoofing (AS), thus denying the true P-code to civilian users. Under such conditions the Trimble 4000SST receiver switches to L2 squaring mode. This tracking process is inherently noisier than the cross-correlation technique (Leick, 1994), used in the previous years. However this was not seen in the results. Average rms of the residuals and differences between the solutions in 1994, were noticeably smaller than the previous year (table 6.1). This was not expected.

### 6.2 Baseline Repeatability (Campaigns 1992-1994)

Twenty five baselines were observed more than once during the 1992 campaign. Repeatability was poor in both software, due to one solution being weak in half of the cases. Thus average repeatability (mean values) in the baseline lengths and elevations differences were artificially high for 1992. Other statistics were calculated, such as the variance and median, but all gave similar values as the mean for 1992 . Table 6.2 shows average repeatability in the latitude (phi), longitude (lambda) and height components for all solutions types and years.

Of the 90 observed baselines, 33 could be processed in dual frequency mode. Processing of the baselines in the TRIMMBP software using the L0 combination, proved fairly straight forward. Repeatability, although a small sample ( 9 repeated baselines), appeared better (table 6.2).

| \eam | Solnaing Type |  | IPHAK <br> Rejected | Remantaily <br> Phis (nmin) | Reprathalle <br> Lambla (cmin) | सenumbuly <br> He ight ( amm |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1992 | TRIMMBP L1 | 18 | 12/210 | 49 | 150 | 96 |
| 1992 | GPPS L1 | 24 | 30/2400 | 27 | 70 | 75 |
| 1992 | TRIMMBP L0 | 28 | 140/2400 | 29 | 25 | 54 |
| 1993 | TRIMMBP L0 | 23 | 40/2900 | 19 | 16 | 39 |
| 1993 | GPPS L3 | 17 | 20/2900 | 11 | 43 | 38 |
| 1993 | GPPS L1 | 23 | 20/2900 | 17 | 20 | 33 |
| 1994 | TRIMMBP L0 | 23 | 30/3000 | 16 | 16 | 36 |
| 1994 | GPPS L3 | 11 | 20/3000 | 11 | 32 | 26 |

Table 6.2. Mean repeatability, in the baseline components.

Day to day repeatability improved drastically in 1993, with all solutions giving similar values. The phi components were strongest, and height the weakest, as expected. The L3 solutions showed a significant weakness in the lambda component. In 1994, average repeatability in the GPPS L3 solutions was slightly better than in 1993, whilst the TRIMMBP L0 solutions gave very similar values to the previous year.

### 6.3 Test Baselines

Results for the six baselines frequently observed during late 1991 and 1992 are discussed. All baselines were processed using the GPPS software, mainly to examine the residual plots. Three solution types were employed, L1 single frequency; L3 ionospheric free combination and L0 wide-lane ionospheric free combination, as discussed in section 4.3.

One baseline was processed in TRIMMBP using the L0 wide lane combination.

Analysis of the baseline solutions showed some interesting results in the GPPS solutions. Firstly, it was revealed that the L1 baseline length solutions provide very noisy, almost random, results compared to L 3 and L 0 . This is to be expected, due to the non treatment of the ionospheric effect. It is hoped that for short baselines up to 20 km , the effect would be similar at both receivers, and thus cancel out. However for the Lago de Maracaibo area, this is not so, and the use of dual frequency receivers is paramount to a meaningful study of subsidence. Single frequency solutions were weakest between days 50 and 200, of the year. Before and after these dates, a reasonable agreement was seen. The dual frequency solutions gave much better results, with L0 slightly more consistent than the L3 solutions, although a couple of solutions still contained spikes (0600-0700 and 0600-0184, on day 365). Baseline lengths in all L 1 solutions varied by $10-30 \mathrm{~cm}$. L 3 solutions varied 210 cm in baseline length throughout the year, whilst L0 varied only $2-3 \mathrm{~cm}$, after accounting for any linear trend. Some definite linear changes in baseline length can be seen in three of the solutions, all showing changes of approximately $5 \mathrm{~cm} /$ year. No correlation between the noisy L1 data and the baseline length or azimuth could be seen.

Changes in elevation difference were not so clear even in the L0 and L3 solutions. All solutions showed great variation in the four baselines, from $2-10 \mathrm{~cm}$, masking any subsidence trend. A distinct correlation between the L0 and L3 results can be seen, and both show the same fluctuations. Thus it would appear that both L3 and L0 are free of biases in the horizontal, but both suffer a similar bias in the height.

The one baseline processed in the TRIMMBP software ( $0600-1010$ ) showed fairly good agreement with GPPS. L1 results generally differed by a few centimetres, at each epoch, but some obvious differences occurred on a few days. L3 results agreed very well (up to 1 cm ) in both baseline length and elevation difference, except on day 63 , where the difference reached 10 cm , in the length. L0 results showed a bias in the length, with the TRIMMBP L0 (wide lane) giving 2ppm longer baselines than the GPPS L0 (wide lane ionospheric free) solutions.

### 6.4 GPPS Double Difference Residual Plots

Analysis of the 1992 double difference residual plots from GPPS L1 showed a variety of trends, between $4-8 \mathrm{~cm}$, on nearly all the baselines, with a few baselines reaching 16 cm . These extreme cases show distinct correlation with rising or setting of the satellite. Some examples of residual plots for the years 1992 and 1993 are given in appendix D.

1993 GPPS L1 double difference residual plots contained trends equal to those of 1992 $(2-8 \mathrm{~cm})$, without the extreme cases, although rms of the residuals and ISR were on the whole better. L3 plots were generally very good, slightly noisier than L1, but showing no short term trends. A few baselines showed some longer term trends up to 4 cm .

Residual plots for the 1994 GPPS L3 solutions were generally good, and very similar to those of 1993, again with some baselines showing some longer term trends, up to 4 cm . Frequent gaps in the data were prevalent in some plots, which is expected with squared data. A test for multipath could be carried out on fifteen of the 1992 and 1993 baselines,
by examining the same baselines, observed at similar times on consecutive days, and repeated trends up to about 2 cm were seen on three lines.

### 6.5 GPS Height Misclosures

Independent height misclosures were calculated from twenty five triangles in the network, for all solution types. The average misclosures are summarised in table 6.3. As a rough guideline, an acceptable misclosure of 1 ppm per baseline was assumed, which translates to 1.7 ppm over three baselines, assuming the random propagation of errors. Both the 1992 L1 solutions exceed this tolerance, with the TRIMMBP processor giving slightly worse closures than GPPS. All solution types in 1993 and 1994, including L1, gave similar average misclosures, within each year. A noticeable improvement is seen from 1993 to 1994. Similar misclosures between single and dual frequency solution types in 1993, suggests that the errors are not frequency dependent.

| Year | Solition ypes |  | Hermeno Mean. (ejum) |
| :---: | :---: | :---: | :---: |
| 1992 | TRIMMBP L1 | 3.10 | 2.30 |
| 1992 | GPPS L1 | 1.90 | 1.35 |
| 1993 | GPPS L1 | 0.74 | 0.56 |
| 1993 | GPPS L3 | 0.71 | 0.55 |
| 1993 | TRIMMBP L0 | 0.75 | 0.54 |
| 1994 | TRIMMBP L0 | 0.38 | 0.33 |
| 1994 | GPPS L3 | 0.46 | 0.45 |

Table 6.3. Average GPS height misclosures. (Approx. 30km triangles).

### 6.6 Post Adjustment Analysis

All campaigns were put through a 3D Cartesian adjustment, using a minimum constraint, fixing station 0202. In 1992, the L1 fixed ambiguity solutions were used. Residuals of the XYZ baseline components were poor in 1992, often up to 5 cm and higher. GPPS L1 contained noticeably larger residuals than the TRIMMBP L1. Some baselines had to be rejected. The author tried to mix float and fixed solutions into one adjustment, but the few float solutions chosen over their fixed counterpart, came up with very large residuals.

An attempt was also made with the 1992 data, to adjust a combination of single and dual frequency solutions, but to no avail. Adjustment residuals of the baseline components were between $5-20 \mathrm{~cm}$, some higher, for nearly all the baselines, indicating a large difference between the two solution types.

In 1993, residuals were much lower, generally up to 2 cm , with only a few reaching 5 cm , in all solutions types, L1 included. No baselines had to be rejected. Residuals in 1994 were of the same magnitude as 1993, which again was not expected, with the squared data.

A posteriori variance factors varied widely, between solutions types and processors, indicating incorrect baseline weights (table 6.4). Campaigns 1990 and 1991 were processed using an earlier version of the Trimvec software, which may account for the significant difference from 1992. All latter TRIMMBP L1 and L0 weights were over optimistic. GPPS L3 solutions gave reasonable results.

| Year | Softwaremod Solution Type |  Hactor: |
| :---: | :---: | :---: |
| 1990 | TRIMMBP L1 | 0.3 |
| 1991 | TRIMMBPL1 | 0.3 |
| 1992 | TRIMMBP L1 | 48.5 |
| 1992 | GPPS L1 | 6.6 |
| 1993 | TRIMMBP L0 | 333.8 |
| 1993 | GPPS L3 | 0.6 |
| 1993 | GPPS L1 | 5.1 |
| 1994 | TRIMMBP L0 | 256.6 |
| 1994 | GPPS L3 | 0.8 |

Table 6.4. Adjustment a posteriori variance factors.

Average relative station error ellipses also varied, mainly between year and solution type (table 6.5). Relative error ellipses were multiplied by the a posteriori variance factor. The 1992 GPPS L1 gave the largest ellipses. 1993 GPPS L1 and TRIMMBP L0 gave the smallest. Again, the GPPS L3 solutions showed a bias in the lambda component, most likely due to the prominent $N / S$ direction of the satellites.

| \ear | Solution Tyee |  |  |  ( mm ) |
| :---: | :---: | :---: | :---: | :---: |

| 1994 | GPPS L3 | 11 | 45 | 19 |

Table 6.5. Average relative station error ellipses (@95\%, for a 10 km baseline).

Final adjusted co-ordinates for all years are tabulated in tables B1 to B9, in appendix B. Average differences in final adjusted co-ordinates are tabulated in table 6.6. Horizontal displacements between all years are plotted in figures B1 to B7, appendix B. Vertical displacements for years 1992 to 1994 are tabulated in table 7.1. In most cases, horizontal displacement fields show systematic scale changes and rotations. Comparisons of different solution types, during the same years, also show systematic biases. Table 6.6 shows average differences between the adjusted co-ordinates for different solution types. It can be seen that the single frequency solutions of 1992 agree well in the horizontal components, but not in the height, whilst the opposite is true for the dual frequency solutions of 1993 and 1994. L1 and L0 solutions of 1993 were very weak in the horizontal, but good in the height.

Table 6.6. Mean differences between adjusted co-ordinates.

### 6.7 Evaluation Using MINQE

Overall pooled error ellipses of the relative co-ordinates changes between campaigns, were approximately 5 cm in the horizontal and 7 cm in the vertical, after the removal of biases. The question arises as to why these are so high. GPS observation weights from the
processors are often over optimistic. The use of variance/covariance estimation techniques such as MINQE, may provide some insights into the appropriateness of the weights. The MINQE approach of evaluating the accuracy and error model, is discussed in detail by Chen [1983] and applied by Chen et al [1990a].

The MINQE program [Caissy, 1994] was used to re-estimate the baseline component errors, for the years 1992 and 1993, using the same baselines employed in the adjustments of section 6.6, i.e. the independent lines only. The results of the MINQE assessment are tabulated in table 6.7. MINQE revealed the accuracy to be similar for all solution types and years, estimating the phi and lambda components to be around 14 mm and the height about 30 mm , which is consistent with the values attained in 1990 and 1991 [Chrzanowski et al, 1991]. The 1993 GPPS L3 solution was noticeably higher in the lambda component.

| Yerr |  |  | Mamlun (Man) |  |
| :---: | :---: | :---: | :---: | :---: |
| 1992 | TRIMMBP L1 | 11 | 10 | 23 |
| 1992 | GPPS L1 | 14 | 21 | 28 |
| 1993 | GPPS L1 | 12 | 13 | 29 |
| 1993 | GPPS L3 | 11 | 30 | 33 |
| 1993 | TRIMMBP L0 | 14 | 13 | 33 |

Table 6.7. MINQE assessment of the baseline components. ( 10 km baseline).

Baseline solutions were re-adjusted using the MINQE weights, and displacements and their pooled error ellipses recomputed. No significant changes were seen in the displacements and the error ellipse size, and only some small rotations of the error ellipses
were seen. Thus it would seem that the relative weights of the processors are appropriate, and that scaling by the a posteriori variance factor from the adjustment, is all that is required. The question remains as to why the error ellipses are so high.

In hind sight, considering the size of the network, minimal observation times and the processing procedures used, pooled error ellipses of this size should be expected, i.e. 7 cm over a 70 km network. Which, of course, translates to 1 ppm in the horizontal component. Breaking the so called 1ppm barrier, which has been demonstrated in many case studies over the last few years, will require some changes in the present scenario.

### 6.8 Systematic Biases

### 6.8.1 Biases Between Different Software

This comparison was hindered by a lack of results from common solution types in each processor. Only L1 data from 1992, and some L3 data from the test baselines, was available. From the L1 data, no noticeable difference in the horizontal components could be seen. Average differences in the final adjusted co-ordinates were 8 mm and 12 mm for phi and lambda, respectively. Displacement differences are shown in figure $\mathbf{C 1}$, appendix C. However, adjusted station heights differed on average by 24 mm , reaching 89 mm in one case. These are shown in table C 1 , appendix C. A rotation of $1.5 \pm 0.4 \mathrm{ppm}$ about a north/south axis, was found to exist between the two solutions. A disagreement in the heights would suggest a problem with modelling of the tropospheric delay. The delay itself is frequency independent, thus different combinations of the L1 and L2 signals would be
affected the same. The use of different models could cause such a difference, which is the case between TRIMMBP and GPPS. The use of slightly different default pressure values may also contribute to the problem. These might explain the 1992 differences, but does not explain the good agreement that was seen in 1993 and 1994, with the dual frequency data (cf. section 6.6). Differences in the L3 solutions of the test baselines were already discussed in section 6.3, and none were seen. On the whole it is believed that the two software give compatible results, between similar solution types.

### 6.8.2 Biases Between Different Solution Types

As expected, biases were found between different solution types, for the same year. A comparison between the two dual frequency solutions TRIMMBP L0 and GPPS L3, for 1993, revealed a good agreement in the height component and some significant differences in the horizontal component, mainly in longitude. This resulted in a significant scale bias between the two solutions types. This was unexpected, and it is thought that the TRIMMBP L0 solution does not remove the ionospheric effect as much as claimed. 1994 shows a smaller scale bias, but with an additional rotation. Differences between final adjusted co-ordinates are tabulated in tables C2 and C3, in appendix C, and plotted in figures C3 and C4. A comparison between GPPS L1 and GPPS L3, is shown also, and a scale bias is evident (figure C2, appendix C).

It was expected that the 1994 results (L2 squared data) would give worse agreement than the 1993 (cross-correlated P-code). However this was not the case and differences were smaller in 1994 between L3 and L0, in the horizontal components (table 6.6).

Overall it was found that the single frequency solutions agreed well in phi and lambda but differed slightly in the height. This is most likely due to the use of different tropospheric models, or met. values. The dual frequency solutions showed the opposite trends, indicating that the ionospheric effect is only seen in the horizontal component.

### 6.8.3 Fixed Co-ordinate Bias

The effect of shifting the co-ordinates of the fixed point was seen in the TRIMMBP L1 solutions for 1992. A shift of $0.5^{\prime \prime}(\approx 15 \mathrm{~m})$ was applied to the phi component of station 0202, and reprocessing of the network carried out. Horizontal components changed little, but heights changed significantly, as expected. A rotation of $0.8 \mathrm{ppm}\left(0.16^{\prime \prime}\right)$ about an east/west axis was seen, which corresponds well with Santerre's [1989] value of $0.1 " / 10 \mathrm{~m}$.

### 6.9 Discussion

Overall, the quality of the data has seen a marked improvement since 1992 , which was of very poor quality. This was seen through very poor day to day repeatability of the baseline solutions, noisy residual plots and large vertical loop misclosures. Results from 1992 were weak in all three components. Thus it is expected that the problems are a combination of
the ionospheric and tropospheric effects. Multipath effects of a few centimetres were seen on a few baselines, which would contribute to the errors, but it is not considered a dominant one.

A comparison of the 1992 GPPS and TRIMMBP L1 results in table 6.1, revealed that large differences were seen between all the components of the baseline solutions (2382 mm ). However, differences between final adjusted co-ordinates were significantly lower in all components $(8-23 \mathrm{~mm})$, indicating the differences to be of a random nature. In 1993 and 1994 this was not quite the case, as differences in the horizontal components barely changed, but an improvement in the height was seen, indicating a systematic difference in the horizontal and again a more random difference in the height.

## Chapter 7

## Deformation Analysis

This chapter examines the displacements given by the GPS, after removing the systematic biases.

### 7.1 Horizontal Analysis

Knowing that systematic biases exist between solutions types, our picture of deformation displacements between two epochs is also likely to be distorted. Figures B1 to B7, in appendix B, derived from the adjusted co-ordinates holding station 0202 fixed, show horizontal displacements between the years 1990 and 1994. Scale biases and some rotations can be seen.

Biases were removed between all years and solution types, to see if better agreement of the displacement field would be seen. This was carried out following the UNB Generalised Method of Deformation Surveys, to obtain a displacement field free of datum distortions [Chen et al, 1990b]. An Iterative Weighted Similarity Transformation (IWST) software provided by Grodecki [1994], was used to remove any systematic translations, rotations
and scale. Figures B8 to B14, in appendix B, show horizontal displacements after the removal of the systematic biases.

Displacements between 1990, 1991, and 1992 became random and insignificant, with only station 0600 showing significant movement (figures B8 and B9). Unfortunately only one solution type was available in each epoch, so no additional comparisons can be made.

The resulting displacements for the years 1992 to 1993, in all cases were very similar, (see figures B10 to B12). This is a good sign, indicating that even single frequency solutions can provide equivalent displacements to dual frequency solutions, if the biases are removed. Unfortunately pooled error ellipses (approx. 50 mm , @95 \%) are too high to show the remaining displacements to be significant. As expected, these are worse for the single frequency solutions. Again, station 0600 showed significant displacement.

Between 1993 and 1994, similar solution types could be compared. However, the two cases did not give similar displacement fields after the IWST, (figures B13 and B14). The displacements are much smaller than previous years, and none are considered significant. Close inspection revealed the GPPS L3 displacements not to change, indicating no bias between the solutions, which is promising. The TRIMMBP L0 displacement field did change, as a definite scale bias was evident. Displacements after IWST were very small, and only station 0600 showed sign of significant movement. Again pooled error ellipses are high.

### 7.2 Vertical Analysis

For the vertical analysis, displacements from precise levelling are available for comparison.
It was hoped that the height differences from the GPS would correlate somewhat with the levelling differences. Table 7.1 shows a comparison of some cases. Very little correlation can be seen, between the early campaigns 1990 to 1993, but a much improved agreement was seen between 1993 and 1994.

Table 7.1. Comparison of GPS and Levelling subsidence.

In all epochs, except 1993 to 1994, the GPS subsidence show uplifts of many of the points, due to tilts in the results. Pooled error ellipses of the subsidence determination, after the least squares adjustments, are on average 70 mm (@95\%).

A test was carried out to remove the subsidence (taken from the levelling results) to see if a common bias would remain. Results are tabulated in table 7.2. Between all years and all solution types vertical rotations about one or both horizontal axis were seen. Rotations vary between $2-7 \mathrm{ppm}\left(0.4-1.4^{\prime \prime}\right)$ and are seen in all solution types. However, a significant decrease is seen between 1993 and 1994, with the dual frequency solutions. The most probable causes of vertical rotations are mis-modelling of the tropospheric delay or ephemeris errors. GPS subsidence before the removal of rotation bias is seen in figure 7.1, for one case.

Table 7.2. GPS vertical rotation between years and solution types.

Taking the differences between the levelling subsidence and the GPS subsidence as true differences, an approximate accuracy for the GPS subsidence, could be estimated. We can also estimate a value for the accuracy of the GPS heights for one campaign, by subtracting the levelling accuracy ( $10 \mathrm{~mm}, @ 68 \%$ ).

$$
\begin{equation*}
\sigma_{\text {GPS }}^{2}=\sigma_{\text {Diff }}^{2}-\sigma_{\text {Lev }}^{2} \tag{7.1}
\end{equation*}
$$

where

$$
\begin{equation*}
\sigma_{\text {Diff }}=\sqrt{\frac{\sum \text { Diff }^{2}}{2 n}} \tag{7.2}
\end{equation*}
$$

The results are tabulated in table 7.3, column one. These are pessimistic estimates as they are contaminated by the rotation biases. Rotations were removed from all cases and GPS subsidence re-calculated. A remarkable improvement was seen in all solution types, bar one.

Table 7.3. Estimated GPS height accuracy ( $@ 68 \%$ confidence), for one campaign, before and after removal of the rotations.

Between TRIMMBP 1993 and 1994, a slight degradation of the accuracy is seen. This is because of one outlier. After its removal, both solution types were at a similar level. GPS subsidence after rotation removal is seen in table 7.4 (all cases) and figure 7.2. GPS height accuracy was re-estimated and is shown in table 7.3, column two.

Table 7.4. GPS subsidence, after removal of vertical rotations (m).

## Costa Bolivar GPS Subsidence Network

Figure 7.1. GPS and Levelling subsidence. 1992 to 1993, before rotation removal.

## Costa Bolivar GPS Subsidence Network

Figure 7.2. GPS and Levelling subsidence. 1992 to 1993, after rotation removal.

It can be seen that the GPS accuracy of the heights for one campaign showed a vast improvement after removal of the rotations. The values attained from the subsidence differences are in stark contrast to the values attained from the least squares adjustments and MINQE analysis of one campaign. It is required that GPS heights for one campaign give an accuracy of $<15 \mathrm{~mm}$ (@68\%). According to the estimates obtained through the subsidence differences, this has been achieved during the last two years.

### 7.3 Discussion

The results have shown that horizontal deformation can be detected regardless of solution type, providing biases are removed from the non ionospheric solutions, i.e. L1 and L0. This was demonstrated in the 1992 test baselines and the campaigns of 1992 to 1994. Vertical subsidence shows very comparable results to levelling, also regardless of solution type, once biases are removed. The last two years saw a drastic reduction in the vertical rotations, decreasing to less than 1 ppm , between the two dual frequency campaigns. This would suggest a possible frequency dependent effect such as the ionospheric delay. Although the estimated accuracy of the GPS heights has approached the required level, without any proper treatment of the tropospheric delay in the post processing stage, further investigation is still required to assess the true cause of the rotations.

## Conclusions and Recommendations

The following conclusions have been drawn from the evaluation of the past five GPS campaigns between 1990 and 1994 .

First and foremost, it would appear that the present GPS methodology, field technique, and post processing employed, is unable to compete with precise levelling at the desired accuracy (subsidence: $20-30 \mathrm{~mm}$, @95\%). Analysis of the error ellipses after the least squares adjustment, reveal that the GPS will provide 50 mm and 70 mm (@95\%) for the subsidence in the horizontal and vertical components, respectively. However, a comparison of the subsidence differences between the GPS and levelling reveal the accuracy to be much better, in the order of 40 mm (@95\%) for the subsidence. Estimates of the last two campaigns have shown an improvement due to less noisy, dual frequency data, from a more complete satellite constellation.

As with previous studies of earlier campaigns, systematic biases, mainly horizontal scale changes up to 5ppm and vertical rotations up to 1.4", still exist in the data. Biases are independent of processor type, considering the two commercial software packages used in this study, but are dependent on the type of processing solution employed. Biases vary
from year to year, and a considerable decrease is seen in the last two epochs. Although large horizontal biases are still evident during this period, these can be handled adequately using a suitable solution type. Vertical rotations were reduced to less than 1 ppm , during these periods of dual frequency data. The cause of this needs further investigation.

Single frequency solutions contain biases in the horizontal and vertical components. The two dual frequency solution types gave very compatible results in the height, and agreed reasonably well with the levelling subsidence, in the last epoch, prior to removal of biases, which is fairly promising. TRIMMBP L0 solutions suffered horizontal scale biases, due to the non treatment of the ionosphere. L3 solutions seemed to be free of horizontal biases, but their larger error ellipses show displacements to be less significant, due to the L3 combination being inherently noisier than other combinations.

The test baselines from 1992 demonstrated that consistent deformation results can be attained in the baseline length, with suitable solution types, but the height component needs modelling to remove rotations. GPPS L0 showed very good agreement with L3, in both baseline length and the height, but both suffered a similar bias in the height, masking the subsidence trend. This is contrary to the reasonable agreement in height attained in later years. Inadequate handling of the tropospheric delay is the suspected cause.

The removal of horizontal biases gave compatible displacements regardless of solution type. This on the whole is also quite promising. However, the poor day to day
repeatability and weak solutions, made for large error ellipses in all solution types, reducing the significance of the displacements.

MINQE analysis gave very similar results for the least squares error ellipses, indicating that software weights obtained from the software solutions for the baseline components are suitable providing one scales the covariance matrix by the a posteriori variance factor from the post adjustment.

Relative accuracy (for two successive campaigns) is deemed to be about 1 ppm and 1.5 ppm in the horizontal and vertical displacements respectively, with the present arrangement. An improved accuracy should be attained with some modifications. Three options are considered.
(1) If commercial software are still to be employed, then longer sessions (possibly 4hrs) or more importantly, extra sessions are needed. At present, each station is only visited once to three times per campaign. All stations should be observed in at least three different sessions. The author feels that a large redundancy of data is important, when using commercial software, in such a situation. In the post processing stage, the use of a widelane ionospheric free combination is very beneficial. The present Trimble software, being employed, does not allow this. However, the new Trimble GPS Survey does allow a similar combination. Although present commercial software provide linear combinations with a long wavelength, fixed ambiguity, and ionospheric reduction, they still lack
adequate handling of the tropospheric delay, which in this case study is quite likely to be a limiting factor.
(2) It is highly recommended by the author that the switch to a more sophisticated, i.e. scientific style, processor be made, if the desired accuracy is to be achieved, in a project of this size and nature. Such software today provide the above linear combinations and allow for stochastic modelling of the tropospheric effect. This should be first tested using the 1993-1994 data sets.
(3) The use of the so called fiducial station strategy would be very beneficial in this network to elliminate the effects of systematic biases, from year to year.

The use of Trimble 4000SST receivers will also be a restricting factor, considering the permanent activation of Anti Spoofing. Upgrading to the much improved Trimble 4000SSE receivers, which can recover the P-code group delay, would be beneficial, and a necessity if the above linear combinations are to be employed.

The overall conclusion is that the use of the GPS in precision geodetic surveys in the hot and humid climate of the equatorial region, still requires further research. The systematic biases (rotations and scale changes) of the GPS network are much larger than those experienced in more moderate climates, as discussed by other authors.

## Appendix A

## Baseline Results 1992 to 1994

#### Abstract

This appendix contains tables of the individual baseline components ( $\delta \phi, \delta \lambda$ and $\delta$ h) for each solution type, during the years 1992 to 1994. Where applicable differences are also given between different solution types.

Note: tables in this appendix may extend over a page.

Table A1. 1992 GPPS L1 and TRIMMBP L1 solutions.
Baseline components in Phi/Lambda/Height, and software differences.

## Appendix B

## Final Adjusted Co-ordinates and Displacements, 1990 to 1994

This appendix contains tables of the final adjusted co-ordinates and plots of the displacements, for the the years 1990 to 1994.

Tables B1 to B9, contain the adjusted coordinates from the minimum constraints adjustment, holding station 0202 fixed.

Figures B1 to B7, contain the displacements from the minimum constraints adjustment, holding station 0202 fixed.

Figures B8 to B14, contain the displacements after the removal of the systematic biases.

Table B1.
Venezuela GPS 1990 (TRIMMBP LI solution) Adjusted PLH Coordinates:

## Appendix D

## Examples of Residual Plots

This appendix contains some double difference residual plots for the years 1992 and 1993. An example of the worst and best plots are given.

According to Ashtech [1993], an L1 cycle is 19 cm and an L3 cycle is 48 cm .

Figure (D2). $\begin{gathered}1992 . \text { Baseline } 0500 \text { to } 1010 . \text { Day } 133-2 \\ \text { SUs } 13 \text { (Li) } 16 \text { 18 } 24-02(1)\end{gathered}$

Epochs (15.00 Seconds Each)

Epochs (15.00 Seconds Each)

Epochs (15.00 Seconds Each)

Epochs (15.00 Seconds Each)

## Appendix E

## Software Comparison to DIPOP

This appendix contains the results of the Texas data set. A table of individual results for each software is given, followed by tables of day to repeatability and internal and external loop misclosures.

Table E1, contains a comparison of baseline solutions from the three processors.

Tables E2 to E7, contain the 3D loop misclosures (external), calculated using independent baseline solutions.

Table E8, contains the 3D loop misclosures (internal), calculated from the baselines within a session.
